This report covers 85 pages.

1 Introduction

The Molas B300 is a lidar system (lidar=light detection and ranging) for wind measurements in the lower atmosphere. This remote sensing device (RSD) has been developed by the Chinese company Movelaser with special intension to the needs of the wind energy industry. This report describes a test of the accuracy of a Molas B300 serial number 4 against conventional wind measurements with mast mounted cup anemometers and conventional wind vanes.

The calibration describes the accuracy of the measurements of the RSD for the environmental conditions present at the test site during the test period. The environmental conditions present at an application of the RSD may deviate from the conditions present at the Calibration Test.

The reported Calibration Test follows the latest requirements as developed in the frame of the ongoing revision of the standard IEC 61400-12-1 [1]. The test took place at a special test station for remote wind sensing devices in Eastern Friesland, where a 135 m high met mast is available, detailed information of the mast [5]. Basis of this report is the calibration certificate RSV17005_Rev_1 [4].

2 Measurement Site and Met Mast

The measurement is located near the village Georgsfeld, approximately 5 km north-west of Aurich, in the region Eastern Frisia, which is in the north west of the German state of Lower Saxony. The distance to the North Sea is approximately 20 km.

The area around the met mast position is characterised by flat terrain. The terrain height at the met mast location is about 6 m above sea level. The best fit of a plane to the terrain up to 5km distance going through the bottom of the mast has no significant slope. The maximum deviation of the terrain to this plane is 11 m.

The landscape is characterised by farmland with closed appearance. The land development in the environment mainly consists of small villages, with tree rows along roads and field borders. Noteworthy are the town of Aurich (40 000 inhabitants) 5 km to the South East and a forest 1 km to the North West. In a distance 70 m to the mast an earth dike with low trees runs from South West to North East.

A map of the measurement site is given Figure 2.1. Photos of the met mast and a panoramic view of the site are shown in Figure 2.2 and Figure 2.3.

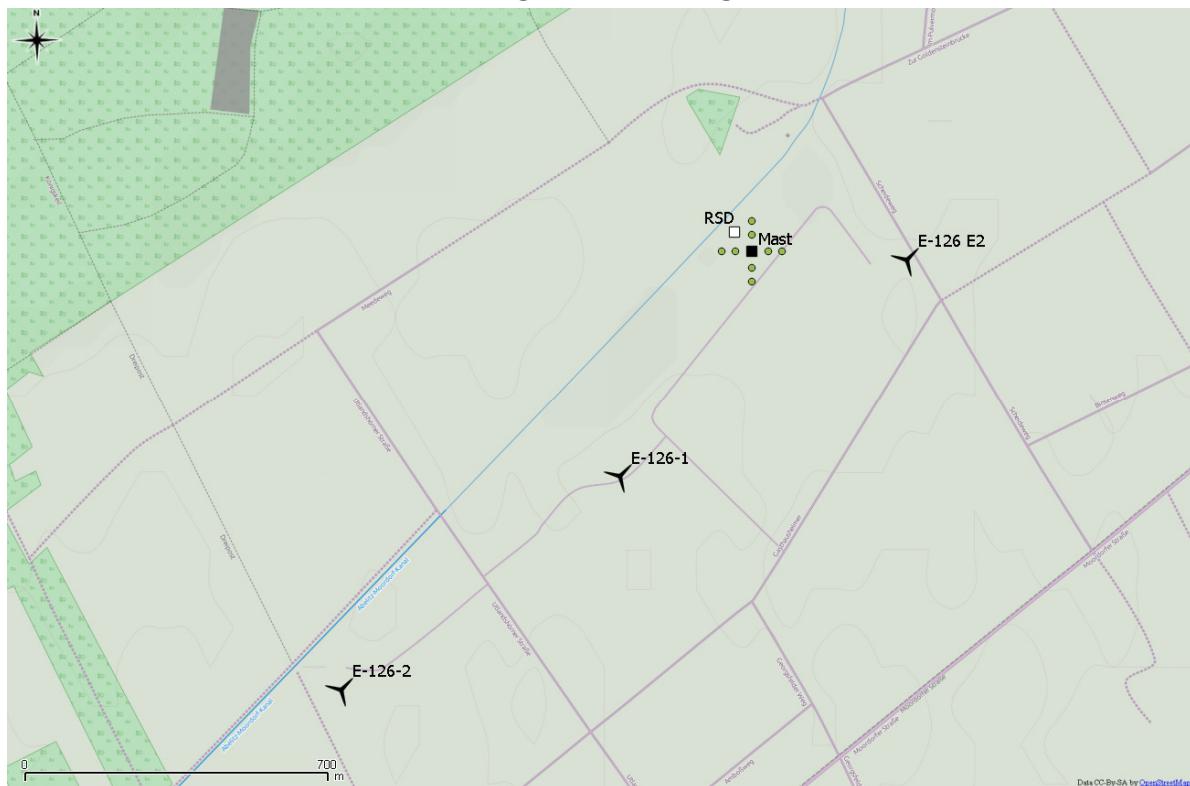

Figure 2.1: Map of the measurement site. The wind turbines E-126 limit the measurement sector. The met mast is marked by a black square with the black dots marking the anchor points of the guy wires. The RSD was located about 58 m northwest of the met mast. The maximum measurement sectors for the test are 242° to 58° and 133° to 178°. The maximum measurement sectors for the test are 242° to 58° and 133° to 177°

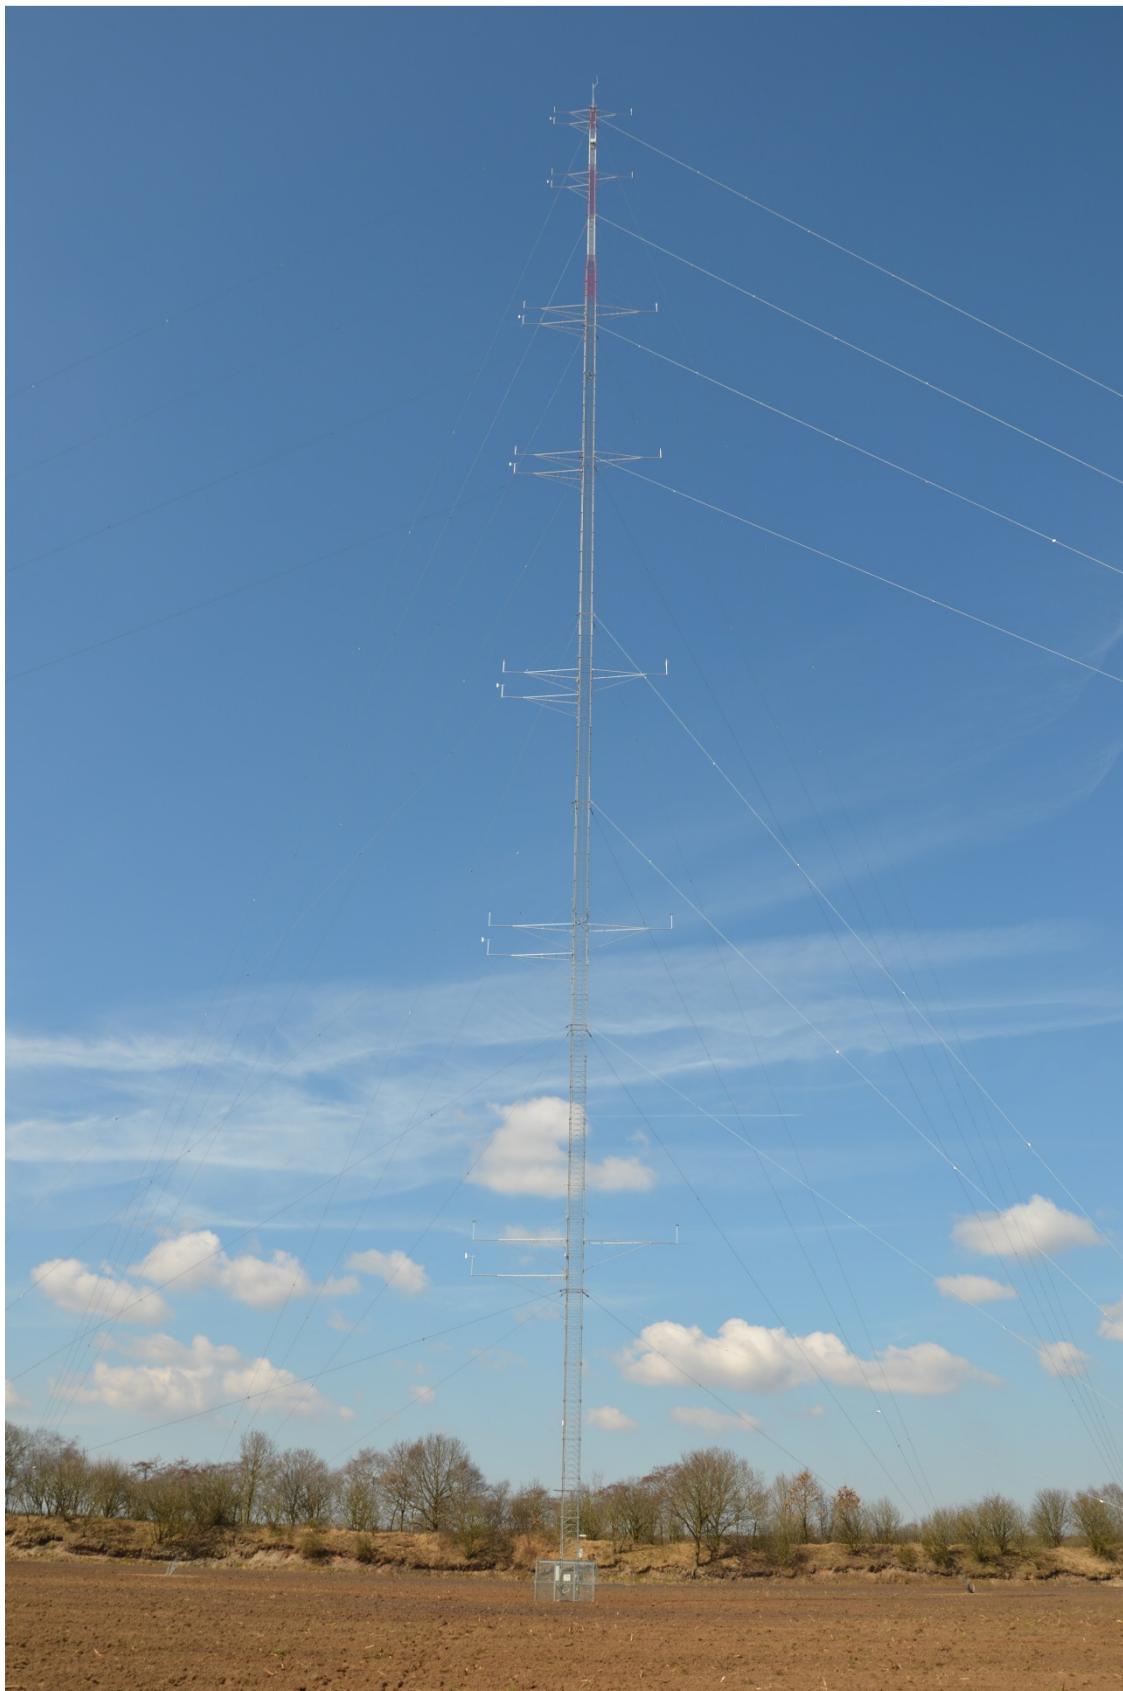

Figure 2.2: Photo of the 130 m high met mast near Georgsfeld, looking in direction southwest.

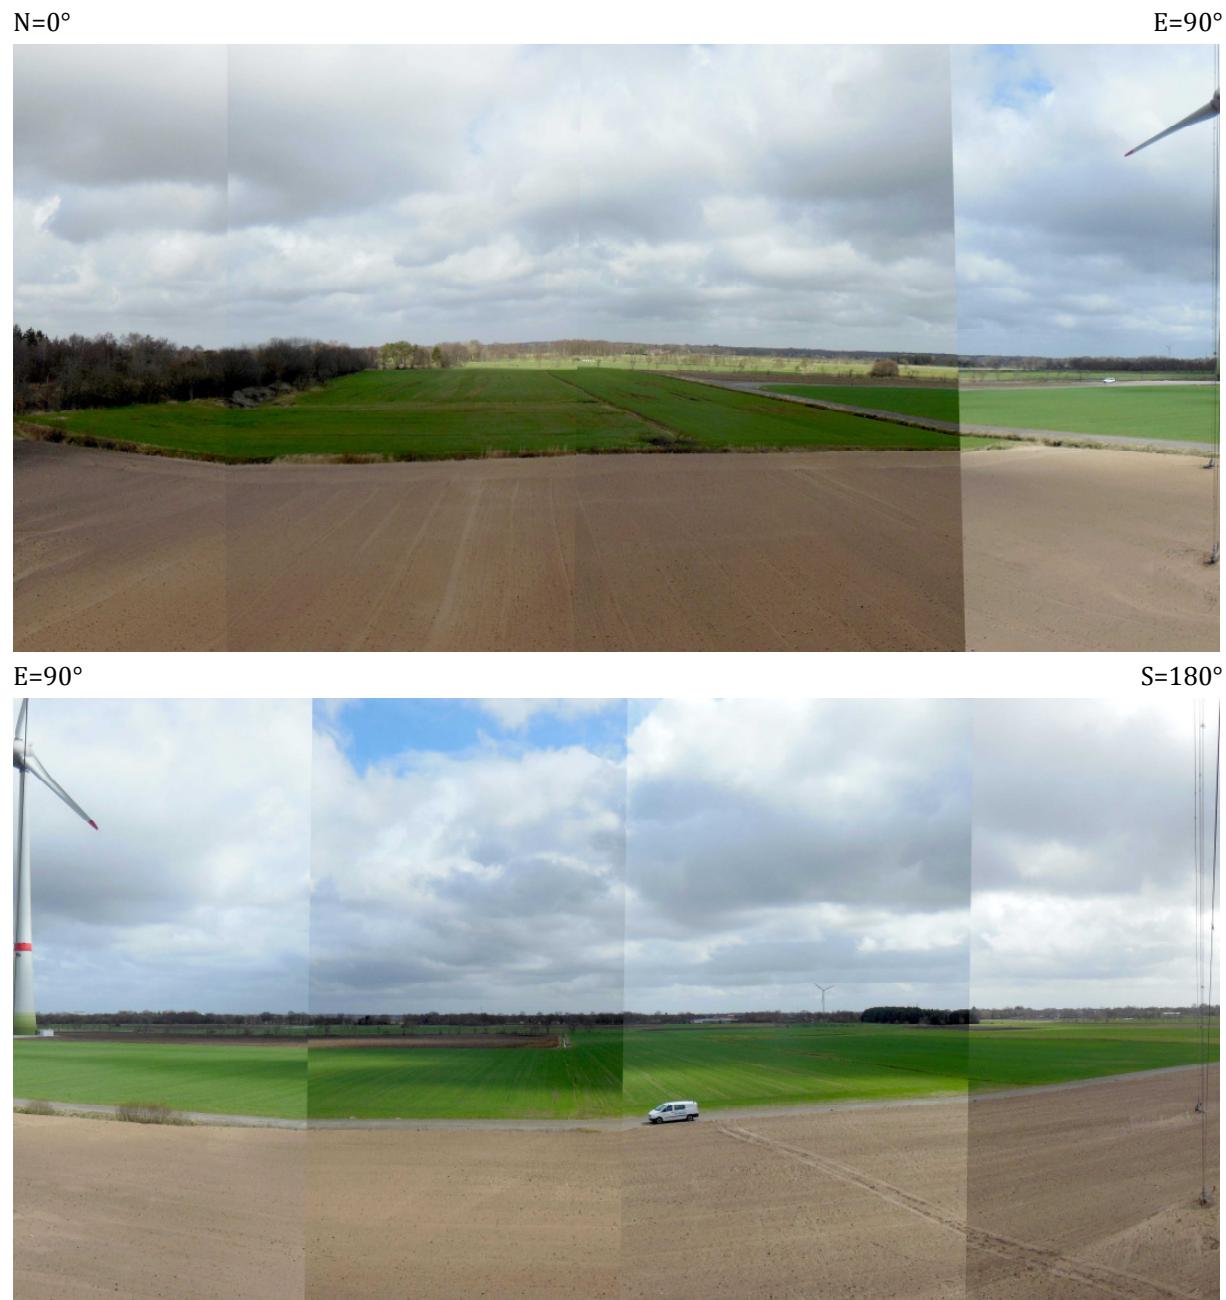

Figure 2.3: Panoramic view of the measurement site taken 13 m from the bottom of the met mast (continued).

Figure 2.3: Panoramic view of the measurement site taken 13 m from the bottom of the met mast (end).

During the measurement, the RSD was installed in a fenced area about 58 m next to the met mast (Figure 2.4).

The met mast is positioned about 357 m west of a test wind turbine. The test wind turbine and other neighbouring turbines influence the airflow at the mast at easterly and south westerly wind directions. The coordinates and the resulting wake effects calculated according IEC 61400-12-1 for power performance measurements [1] can be seen in detail in Table 2.1. From all these wakes, an undisturbed and applicable sector of 242° to 58° remains for testing the RSD. The measurement sector must be reduced further for some reference sensors due to mast effects (see Table 2.2).

Figure 2.4: The RSD under test installed next to the met tower.

The met mast is equipped with several cup and ultrasonic anemometers as well as wind vanes in different heights above ground. The airflow at the positions of the anemometers and vanes is significantly influenced by flow disturbance caused by the mast and neighbouring sensors (blockage effects, flow acceleration effects). The least influence occurs at the cup anemometer of type Thies First Class Advanced which is mounted at 135 m height above ground at the top of the met mast. An individual wind direction depending correction has been applied to the wind speed measurements of the cup and ultrasonic anemometers which are mounted on side booms to the mast (all mounting heights except 135 m). Those correction functions have been determined empirically. The cup anemometers are of class 0.9A according to reference [1], [2]. The cup and also the ultrasonic anemometers have been calibrated in a wind tunnel according to DKD and MEASNET [3]. One of the calibration wind tunnels of DWG is applied by the German authority for controlling units, Physikalisch-Technische Bundesanstalt (PTB), for defining the unit m/s in airflow measurements. A more accurate tracing back of the anemometer measurements is currently not possible. The ultrasonic anemometers were calibrated for different horizontal and vertical orientations. The wind measurements with the mast follow the requirements of IEC 61400-12-1[1].

A list of the undertaken comparisons of sensors of the met mast and measurements of the RSD are given in Table 2.2. From the table, the disturbed sectors caused by the mast and the neighbouring turbines and the chosen evaluation sectors can be seen. The positions of the lidar beams in dependence of the measuring height have been taken into account for the calculation of the disturbed sectors. Table 2.3 shows the specifications of the sensors mounted at the met mast.

The RSD provides measurements only for heights above ground in integer multiples of meters, i.e. not exactly at the heights of the reference sensors of the mast. The measurements of the RSD have not been interpolated to the exact heights of the reference anemometers. The minimum measurement height of the RSD is limited to 40 m. For the comparison of the measurements of the RSD to the measurement of the cup anemometer the measurements of the met mast were interpolated to measurement height levels of the RSD by the application of a power law fitted to each individual 10-minute data set.

Object	Position		Rotor diameter D	Distance from met mast	Direction from met mast	Met Mast in Wake

Table 2.3 Sensor specification list of mast mounted sensors which were used for calibration.

3 Set-Up of the RSD, Data Collection and Data Processing

3.1 Set-Up of the RSD

The evaluated measurement period was from 2017-02-11 to 2017-03-15. The RSD was supplied by 230V/AC. The basic information and key settings of the RSD are shown in the following table. The settings have not been changed in the measurement period.

Evaluated measurement period	2017-02-11 to 2017-03-15
RSD model	Molas B300
Unit serial number	4
Beam angle from vertical	28°
Selected measurement heights	40.75 m, 60.75 m, 81.75 m, 100.75 m, 120.75 m, 130.75 m, 134.75 m
Height difference between RSD and Mast	0.75m
North orientation during test	337°
Power supply	230V
Firmware	2.1.1

Table 3.1 Basic information and key settings of the tested RSD

The vertical and horizontal alignment of the RSD was adjusted by staff of Movelaer at the start of the measurements. The alignment was measured with a water spirit level. The horizontal orientation was controlled by a compass. The alignment did not change during the course of the measurements.

The data acquisition system of the met mast has been synchronised to CET, the RSD has been synchronised to CET+7. During the measurement period, the time was synchronised by internet via GSM connection.

3.2 Data Collection

The RSD stores the data files containing statistics of 10-minute periods by an internal computer. The measurement data of the RSD was sent by email.

3.3 Data Processing

3.3.1 Interpolation of Horizontal Wind Speed Component and its Standard Deviation as Measured by Anemometer

The RSD allows measurement height selection only in integer meter values. To evaluate the horizontal wind speed of same height levels the wind speeds of cup anemometers have been interpolated.

For this, a power law has been adjusted to the measurements of the horizontal wind speed component of cup anemometer for adjacent sensors (e.g. 100.3 m and 82.2 m) measurement height within each 10-minute period:

$$\alpha_v = \frac{\ln\left(\frac{v_{Anemometer,h_1}}{v_{Anemometer,h_2}}\right)}{\ln\left(\frac{h_1}{h_2}\right)} \quad (1)$$

$$v_{Anemometer,interpolated} = v_{Anemometer,h_1} \left(\frac{h_{interpolation}}{h_1} \right)^{\alpha_v}$$

where

- α_v : power law exponent in terms of the horizontal wind speed component
- h_1 : measurement height of anemometer below height of reference
- h_2 : measurement height of anemometer above height of reference
- $h_{interpolation}$: interpolation height
- $v_{Anemometer,h_1}$: measurement of horizontal wind speed component of anemometer at height h_1
- $v_{Anemometer,h_2}$: measurement of horizontal wind speed component of anemometer at height h_2
- $v_{Anemometer,interpolated}$: interpolated wind speed

3.3.2 Correction of Wind Speeds Measured by Boom Mounted Anemometers

The anemometers on the mast mounted below the mast top are influenced by the flow blockage effects and flow acceleration effects caused by the mast. These mast effects on the anemometer measurements have been corrected by empirically determined corrections.

3.3.3 Wind Shear

A power law has been adjusted to the measurements of the horizontal wind speed component of the RSD at two measurement heights as close to a pair of successive measurement heights at the met mast within each 10-minute period (see eq. (1)). The wind shear exponents determined from the measurements of the RSD have been compared to the wind shear exponents determined from the mast measurements.

3.3.4 Wind Direction

The wind directions measured by the RSD as average of 10-minute periods have been compared directly to the measurements with the vanes at the nearest measurement heights of the mast. Small deviations in the measurement heights of the RSD and the heights of the reference sensors on the mast have been ignored.

3.4 Data Filtering

The following data filtering has been applied for the comparison of the measurements of the RSD and the mast based sensors:

- Only wind directions, where the RSD and the reference sensor are exposed to free wind conditions (no wake effects), have been considered, i.e. the measurement sector according to Table 2.2 has been applied.
- Only wind speeds above 4 m/s as measured by the reference anemometer have been considered for the following reasons:
 - The wind tunnel calibration of the cup anemometer has been performed in the wind speed range 4-16 m/s according to MEASNET [3]. Despite the limitation of the wind tunnel calibrations to 16 m/s, the wind speed was not limited for testing the RSD in order to gain indications for the accuracy at higher wind speeds.
 - At low wind speeds, the cup anemometer measurements are linked to higher uncertainties.
 - Lower wind speeds are less relevant as hardly any energy is produced by wind turbines below 4 m/s.
- Only 10-minute periods, where the availability signal of the RSD is >80 have been considered.

It is noted that the derived results are valid only for these filters. Thus, the evaluated accuracy of the RSD can be expected in a later application only if the above filter on the availability signal of the RSD is applied.

3.5 Measurement uncertainties

As the measurements with the cup anemometers are traced back to national standards, the comparison between the cup anemometers and the RSD can be used in order to define an uncertainty of the wind speed measurement of the RSD. According to IEC 61400-12-1, ed. 2, [1] the uncertainty components as listed in Figure 3.1 have been considered in order to evaluate the uncertainty of the measurements of the RSD.

The uncertainties are considered to be independent from each other. Thus the combined uncertainty is the square root of the summed squares of the uncertainty components. The components of the uncertainties are explained in the following subchapters.

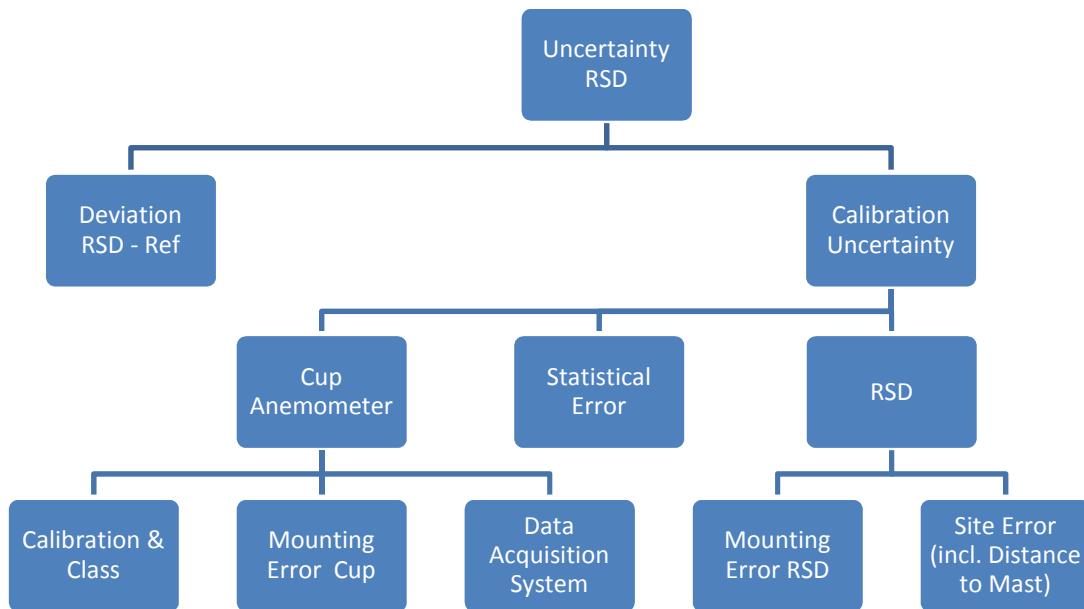

Figure 3.1 Illustration of uncertainty components of final RSD uncertainty.

3.5.1 Measurement uncertainties of the reference anemometer

(a) Calibration of the reference anemometer

The uncertainty of the calibration of the reference is:

$$U_{calibration} = u_{cal}/U_i$$

With $u_{cal} = 0.025 \text{ m/s}$ and U_i as averaged wind speed for respective wind speed class

(b) Classification of the reference anemometer

The sensitivity of the reference is considered according [1], Annex I by an anemometer classification. For the standard uncertainty of the classification is obtained with:

$$u_{class} = kl * (0.05 \text{ m/s} + 0.005U_i)/\sqrt{3}$$

U_i is the average wind speed of the respective class of wind speed i , and kl is the anemometer class ($kl=0.9$ for Thies First Class Advanced)

(c) Vertical alignment of reference anemometer

The vertical mounting accuracy of the anemometers is assumed with $\pm 1^\circ$.

$$u_{vert,A} = (1 - \cos(1^\circ/\sqrt{3}))U_i$$

(d) Vertical alignment of reference mast

The vertical alignment of the mast is assumed with $\pm 1^\circ$.

$$u_{vert,M} = (1 - \cos(1^\circ/\sqrt{3}))U_i$$

(e) Mast effects top mounted anemometer

The standard uncertainty of the mast effects to the top mounted anemometer are derived from the 1:11 rule, i.e. is a cone adhered of 1:11 an uncertainty of 0.5% will be as-

sumed. For other cosine relations it is assumed that the uncertainty is inversely proportional to the cosine relation. For the met mast in Georgsfeld the uncertainty is:

$$u_{top}=424 \text{ mm}/4670 \text{ mm} * 11 * 0.005 * U_i = 0.0050 * U_i.$$

(f) Mast effects boom mounted anemometer

The flow effects of the mast to the reference anemometer are corrected by internal tools.

(g) Horizontal booms

The acceleration effects of the horizontal boom influences the measurement of the anemometer with 0.5% in a distance of 20 times [1]. For higher distances it is assumed that the influence is inversely proportional to the distance. For a vertical distance of 1000 mm over the horizontal boom with a diameter of 48 mm the following uncertainty results:

$$u_{horAusl}=0.0048 * U_i.$$

(h) Data acquisition system

The Campbell CR1000 has an accuracy of 1 Hz per sample by a range of 1500 Hz. For a Thies First Class Advanced this range corresponds to 75 m/s. For the cup anemometer this results to the data acquisition system to a failure of

$$u_{DAS}=75 \text{ m/s} / 1500 \text{ Hz} * 1 \text{ Hz} / \sqrt{3*600}=0.0012 \text{ m/s}.$$

3.5.2 Statistical Error

The statistical uncertainty of comparison between RSD and reference sensor is determined from the statistical uncertainty of the class average of difference between reference and RSD.

$$u_{stat}=\sigma(\Delta v)/\sqrt{n}$$

3.5.3 Measurement uncertainties of RSD

(a) Vertical alignment of reference anemometer

For remote sensing devices it is assumed that they act cosine-like to marginal tilt. For installation of a RSD device it's generally assumed that an accuracy of 1° is reached. Thus the uncertainty results to:

$$u_{vert,P}=(1-\cos(1^\circ/\sqrt{3}))*U_i$$

(b) Measurement resolution

The data recording of remote sensing devices is saved as ASCII-format. The uncertainties of the resolution of the RSD for a 10-min sample is given by

$$u_{DAS,P}=10^{-n}/(2\sqrt{3}) \text{ m/s}$$

Whereby n is the amount of decimal places of the saved data.

(c) Site effect errors

Due to the spatial separation of the measured volumes of the reference to the RSD, errors arise which are determined by the location. Analog to [1] it is assumed that the failure increases linear with increasing the distance between midpoint of probe volume of the RSD. Thus it results:

$$u_{site}=0.01*d/h*U_b$$

where by h is the measurement height over the ground and d is the horizontal distance between the midpoint of probe volume and the reference.

4 Results of Calibration Test

4.1.1 Availability of the RSD

A total amount of 4719 10-minute periods was covered by the evaluated measurement period.

For availability evaluation the RSD has been considered as measurement without met mast. That means no wind directions or wind speed filters have been applied. The so evaluated data availability at the different measurement heights is shown in Figure 4.1. During the test the lidar operated without malfunction.

As can be seen in Figure 4.1, the availability of horizontal wind speed has very high values of more than 99% for measurement heights between 40 m and 140 m. Above measurement height of 100m the availability begins slightly to decrease.

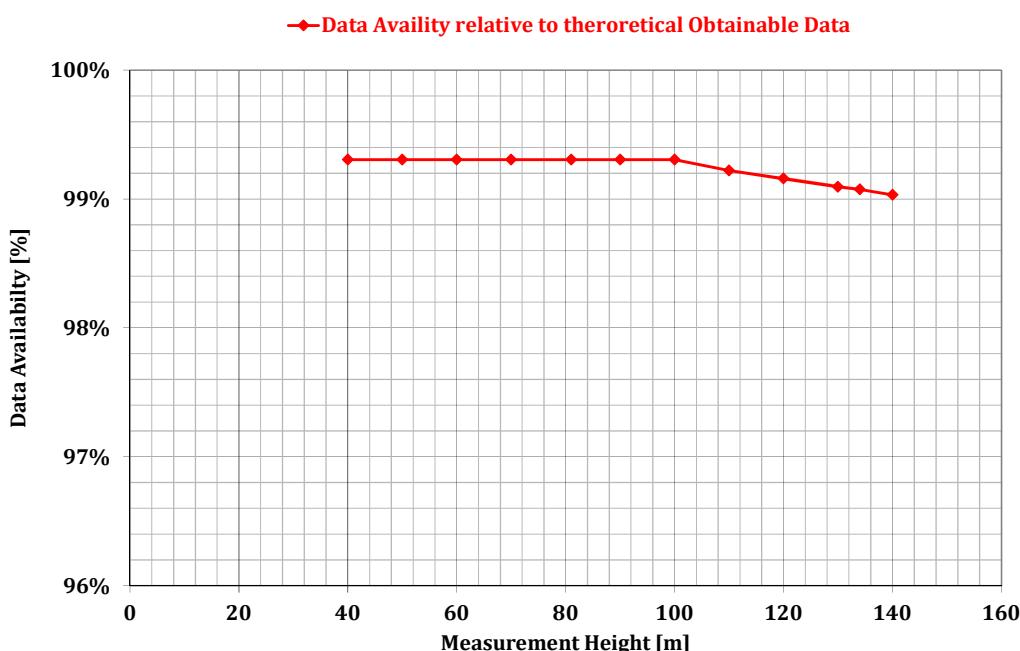

Figure 4.1: Availability of measurement of the horizontal wind speed component at different heights as measured by RSD.

4.2 Accuracy of the RSD in Terms of 10-Minute Averages of the Horizontal Wind Speed

Detailed results of the comparison of cup anemometer measurement and measurement of the RSD in terms of the horizontal wind speed component are presented in the following sub chapters. The results can be summarised as follows:

- For the measurement heights between 135 m to 60 m the 10-minute mean values of the horizontal wind speed component as measured by the RSD and by cup anemometers show an excellent correlation (square of correlation coefficient more than 0.99 - 0.97).
- For measurements height between 135 m and 60 m the horizontal wind speed component of the RSD is marginal underestimated with about -0.1% to - 0.4% or -0.03 m/s to -0.04 m/s.

- For measurements height between 135 m and 40 m the horizontal wind speed component of the RSD show values of standard deviation of deviation of about slightly above 1.9% - 3.4%.
- The scatter plots of horizontal wind speed components show an excellent accuracy with a very good precision.
- The lowest measurement height of 40m is in average underestimated with -2% (Figure 4.15). This deviation could be a result of the lengths of the RSDs probe volumes which may be affected of wake effects of surrounding trees.

As the statistics gained from the 10-minute raw data can in principle be influenced by the distribution of data within the measurement period, the measurements of the RSD have been bin averaged against the cup anemometer measurements, and the bin wise deviation between the measurements has been analysed. For measurement heights between 135m to 60m the bin averaged deviation of the RSD is smaller than the uncertainty of the reference anemometer for most bins (Figure 4.6, Figure 4.8, Figure 4.10, Figure 4.12, Figure 4.14).

As the measurements with the cup anemometers are traced back to national standards, the comparison between the cup anemometers and the RSD can be used in order to define an uncertainty of the wind speed measurement of the RSD. The following uncertainty components have been considered in order to evaluate the uncertainty of the measurements of the RSD:

- Wind tunnel calibration of the cup anemometers
- Classification of the cup anemometers according to IEC 61400-12-1
- Cup anemometer mounting effects
- Uncertainty of correction of mast effects on anemometers
- Bin wise deviation of RSD and cup anemometer measurements
- Statistical uncertainty of bin average of deviation of RSD and cup anemometer measurements

The different uncertainty components have been treated as independent uncertainties for the evaluation of the total uncertainty of the measurements of the RSD as gained from the comparison.

Total results like shown in right column of Table 4.1, etc. are given in expanded uncertainty. The expanded uncertainty assigned to the measurement results is obtained by multiplying standard uncertainty by the coverage factor $k=2$. It has been determined in accordance with DAkkS-DKD-3. The value of the measurand lies within the assigned range of values with a probability of 95%.

The resulting wind speed dependent uncertainties of the measurements of the horizontal wind speed component by the RSD are in the order of about 2% (expanded uncertainty $k=2$) in most wind speed bins for all measurement heights. The variation of the uncertainty reaches from 1.7% to 8.2% (expanded uncertainty $k=2$) for the different measurement heights and wind speed bins (Table 4.1 to Table 4.7).

It is noted that the uncertainty of the RSD as resulting from this comparison does not reflect all uncertainties of the system during an application at another site. The following additional uncertainties should be considered for an application of the system:

- The RSD measurements are influenced by environmental conditions, like e.g. wind shear. Thus, there is an additional uncertainty due to different environmental conditions during the calibration and during the application of the RSD.

- Mounting errors of the RSD during an application (vertical alignment)

Detailed ambient conditions dependent on wind speed and wind direction which were present during the test can be seen in Appendix A.

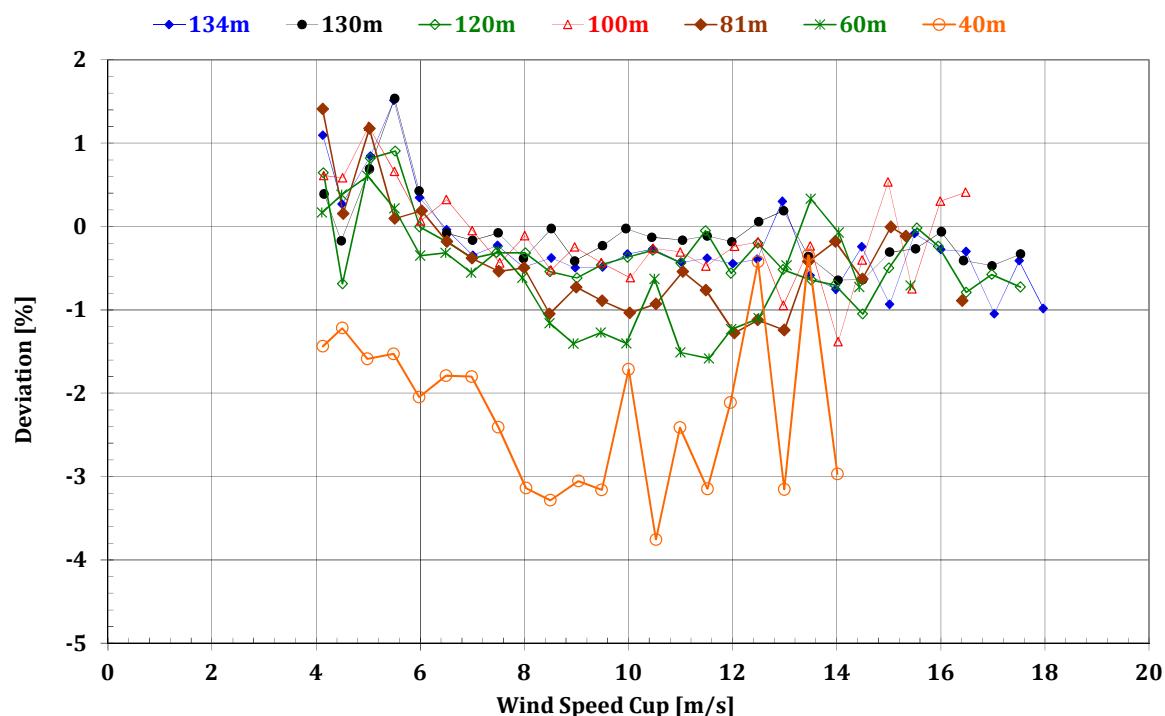

Figure 4.2 Overview of bin averaged deviations of 10-minute averages of the horizontal wind speed component measured by RSD against cup anemometer measurements at several heights. A positive sign of the shown deviation represents higher values measured by RSD.

4.2.1 Accuracy of RSD in Terms of 10-Minute Averages of the Horizontal Wind Speed Component at 134.75 m Measurement Height

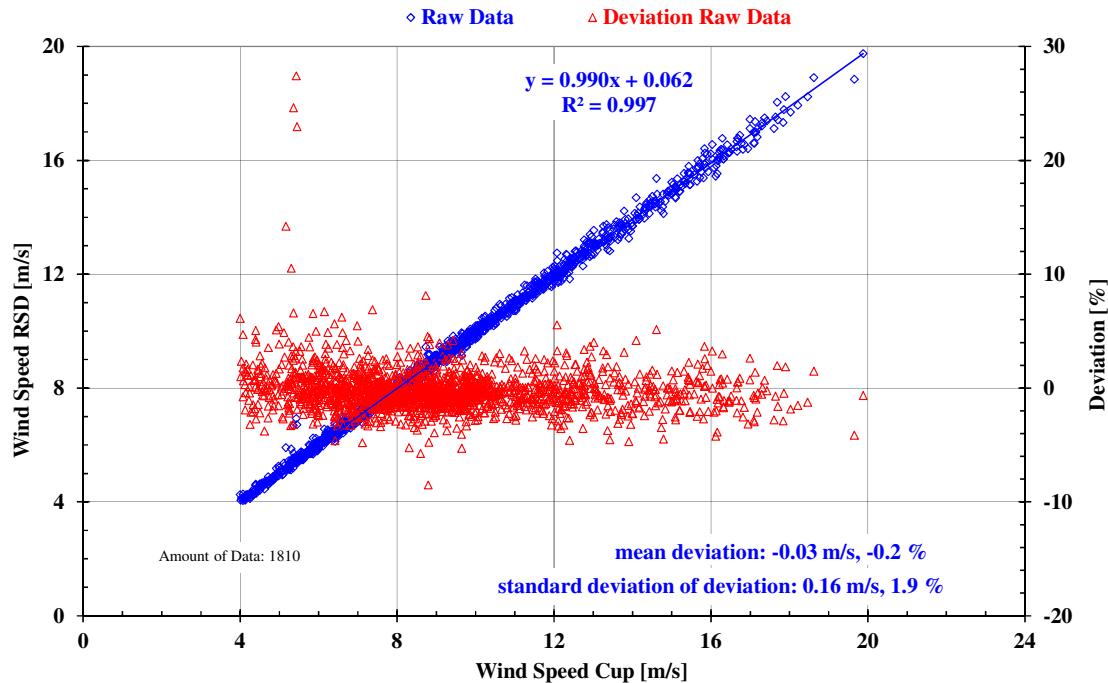

Figure 4.3 Scatter plot of horizontal wind speed component as measured by RSD against cup anemometer readings at 134.75 m height above ground and the deviation between both values in percent of the wind speed. Each point represents a 10-minute average.

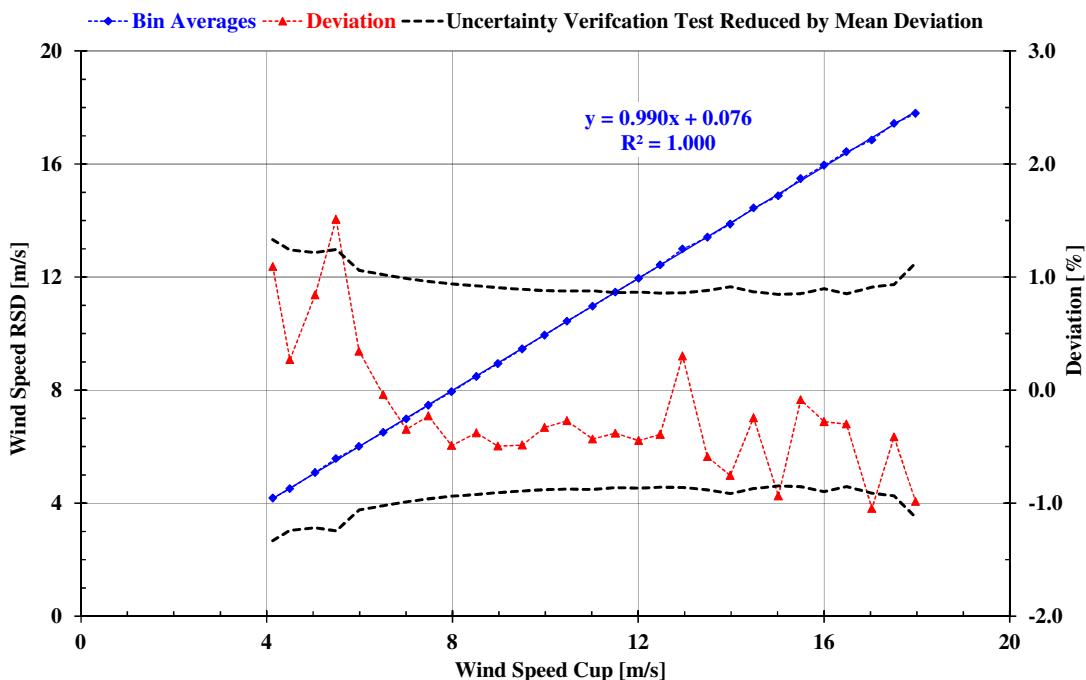

Figure 4.4: Bin analysis of 10-minute averages of the horizontal wind speed component measured by RSD against cup anemometer measurements at 134.75 m height above ground. A positive sign of the shown deviation represents higher values measured by RSD.

A positive sign of the shown deviation represents higher values measured by RSD. The right column shows the total expanded uncertainty (k=2) of the RSD as derived from the test.

4.3 Accuracy of the RSD in Terms of Wind Shear

Wind shear exponents have been calculated for each 10-minute period from the measurements of the RSD and the measurements of the met mast at nearly same measurement heights as explained in chapter 3.3.3.

Detailed results of the comparison of shear exponents are presented in the following sub chapters.

The following conclusions can be drawn:

- The comparison of the shear exponents derived from the measurements of the RSD and the cup anemometer measurements for each 10-minute period shows pleasurable to good correlations from about 0.85 to 0.91 (Figure 4.17, Figure 4.19, Figure 4.21, Figure 4.23 and Figure 4.25). The square of the correlation coefficient is about 0.9 in the different height ranges.
- The bin-averaged wind shear exponents derived from the measurements of the RSD and the cup anemometer measurements show a very good correlation with a squared correlation coefficient of more than 0.99 for measurement height between 40 m and 135 m.
- For wind shear between 100m – 135m the bin analysed exponents determined by the RSD and the cup anemometers agree well in a essentially range of shear exponents from about 0 to 0.55. Wind shears between 100m – 40m show less consensus.
- The standard deviation of deviation of the mean shear exponents gained by RSD in tendency slightly decrease with increasing measurement height from 0.04 to -0.016.

In all height levels, the bin averaged difference in wind shear exponent between cup anemometers and RSD shows strong wind shear dependence. The RSD overestimates wind shear at low shear exponents and underestimates at high wind shears.

The comparison of the shear exponents measured by the cup anemometers and by the RSD can be used in order to define an uncertainty of the measurement of the wind shear of the RSD. The following components have been considered in order to evaluate this uncertainty:

- Wind tunnel calibration of cup anemometers
- Classification of the cup anemometers according to IEC 61400-12-1
- Cup anemometer mounting effects
- Uncertainty of correction of mast effects on anemometers
- Bin wise deviation of RSD and cup anemometer measurements in terms of the wind shear
- Statistical uncertainty of bin average of deviation of RSD and cup anemometer measurements in terms of the wind shear

The respective uncertainties of the two cup anemometer measurements applied to evaluate the reference wind shear have been cumulated under careful and conservative consideration of the correlation of the uncertainties between the cup anemometers. The uncertainty components listed above have then been treated as independent uncertainties for the evaluation of the total uncertainty of the wind shear measurement by the RSD as gained from the comparison.

The resulting standard uncertainty of the RSD measurements in terms of the wind shear exponents is below 0.12 ($k=2$) for a shear range of 0.0 to 0.6 in all height ranges with the exception of wind shear between 140 m and 120 m. This is considered as good. For negative wind shear and high wind shear above 0.6 uncertainty increases significantly to values of 0.3 and more. This is considered unfavourably for sites with such wind shear conditions.

4.3.1 Accuracy of RSD in Terms of Wind Shear between 134.75 m and 120.75 m

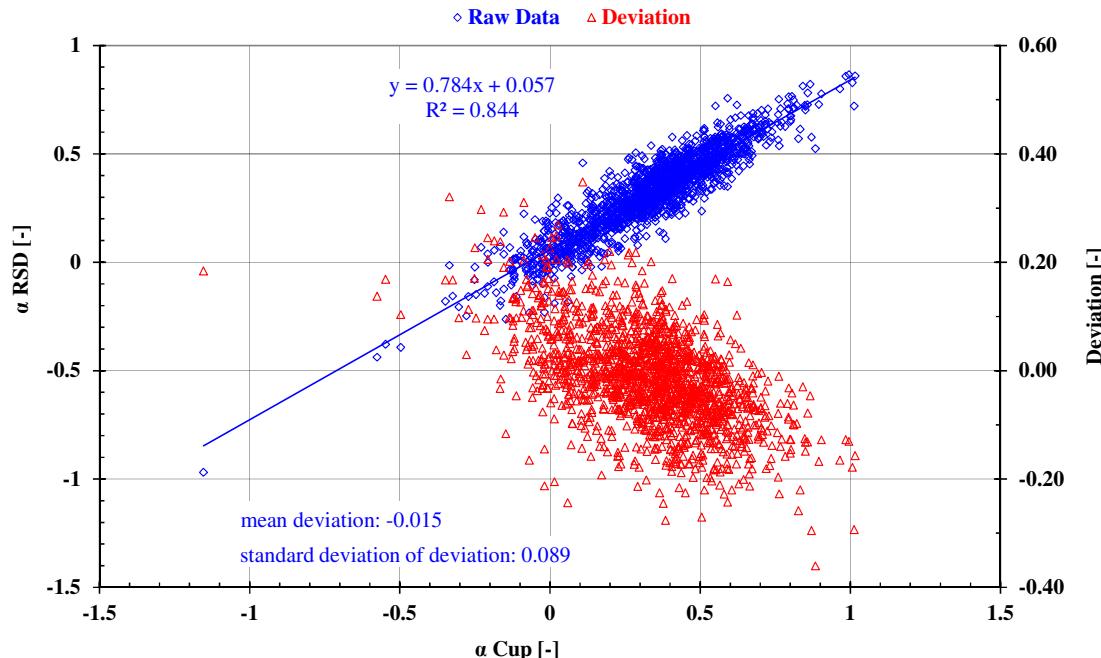

Figure 4.17: Scatter plot of shear exponents as measured by RSD between 134.75 m and 120.75 m height against cup anemometer measurements between 135 m and 120.3 m height and the deviation between both shear exponents. Each point represents a 10-minute period.

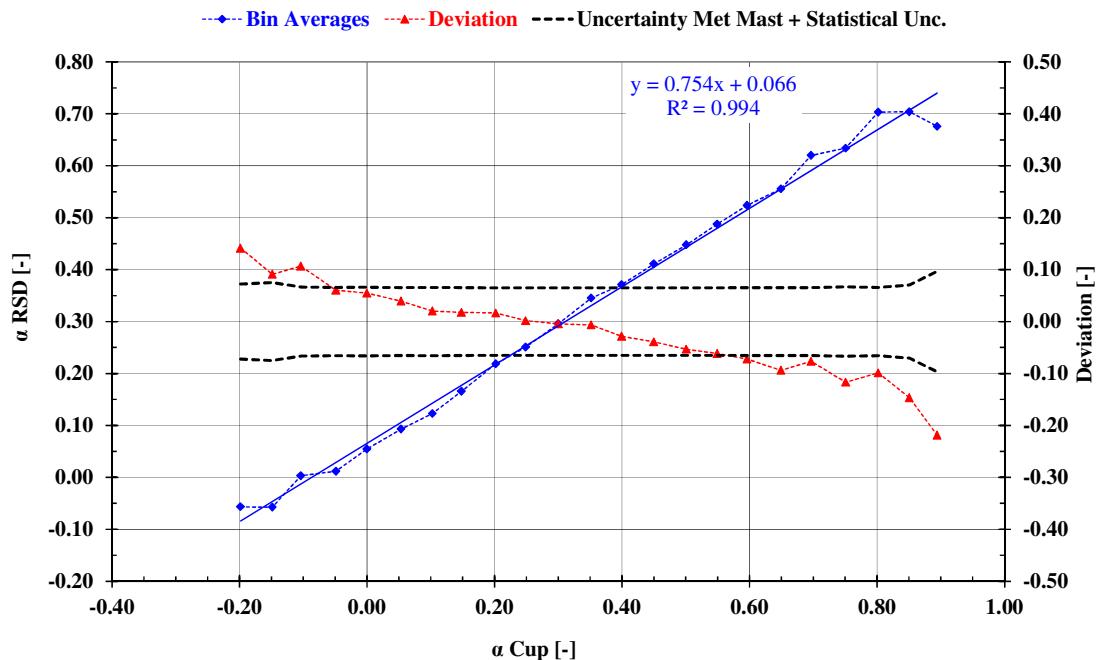

Figure 4.18: Bin analysis of shear exponents measured by RSD between 134.75 m and 120.75 m against cup anemometer measurements between 135 m and 120.3 m height above ground. A positive sign of the shown deviation represents higher values measured by RSD.

A positive sign of the shown deviation represents higher values measured by RSD. The right column shows the total expanded uncertainty (k=2) of the RSD as derived from the test.

4.4 Accuracy of RSD in Terms of Turbulence Intensity

For the evaluation of the accuracy of the turbulence intensity of the horizontal wind speed component per 10-minute period as measured by RSD, the same data filtering as described in chapter 3.4 has been applied. Detailed results of the comparison at all measurement heights of the mast are shown for cup anemometers as references in the following sub chapters. Key results are:

- The correlation of the turbulence intensity as determined by the RSD and the turbulence intensity as determined from cup anemometers is pleasurable (squared correlation coefficient of about 0.76 to 0.88) Figure 4.29, Figure 4.33, Figure 4.35, Figure 4.37, Figure 4.39, Figure 4.41.
- The mean deviation of turbulence intensity determined by the RSD deviates between -0.006 to -0.009 from the reference measurements at the different measurement heights.
- The bin averages of the turbulence intensity as determined by the RSD correlate very good with the bin averages of the turbulence intensities determined with the reference sensors of the met mast with squared correlation coefficients of about 0.99.

4.4.1 Accuracy of RSD in Terms of Turbulence Intensity at 134.75 m Measurement Height

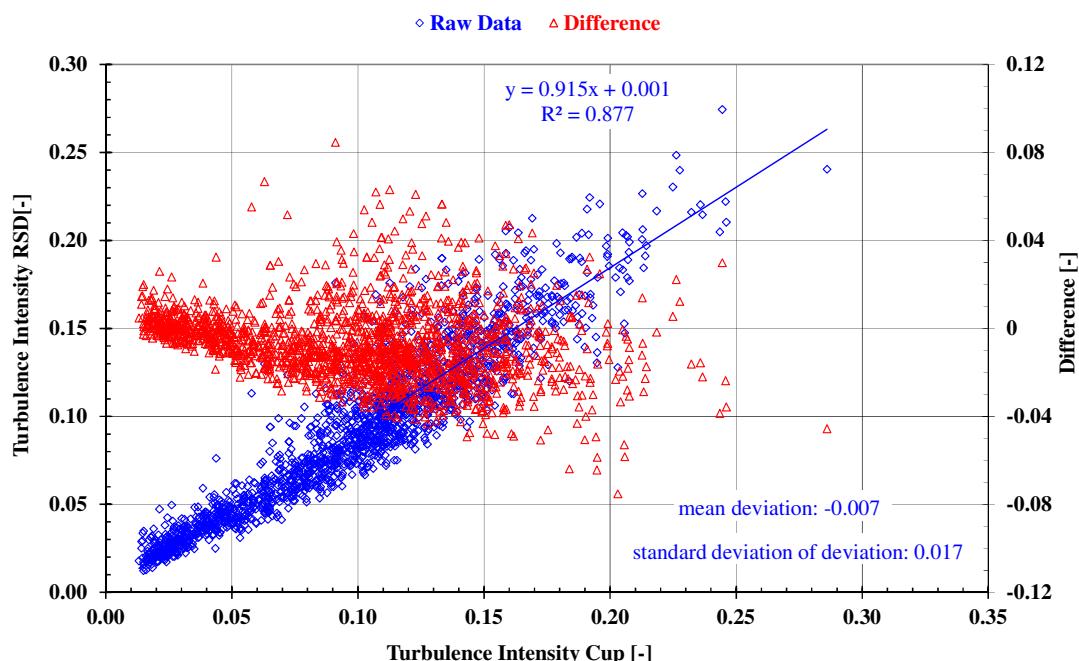

Figure 4.29 Scatter plot of Turbulence Intensity as measured by RSD against cup anemometer readings at 134.75 m height above ground and the deviation between both values in percent of the wind speed. Each point represents a 10-minute average.

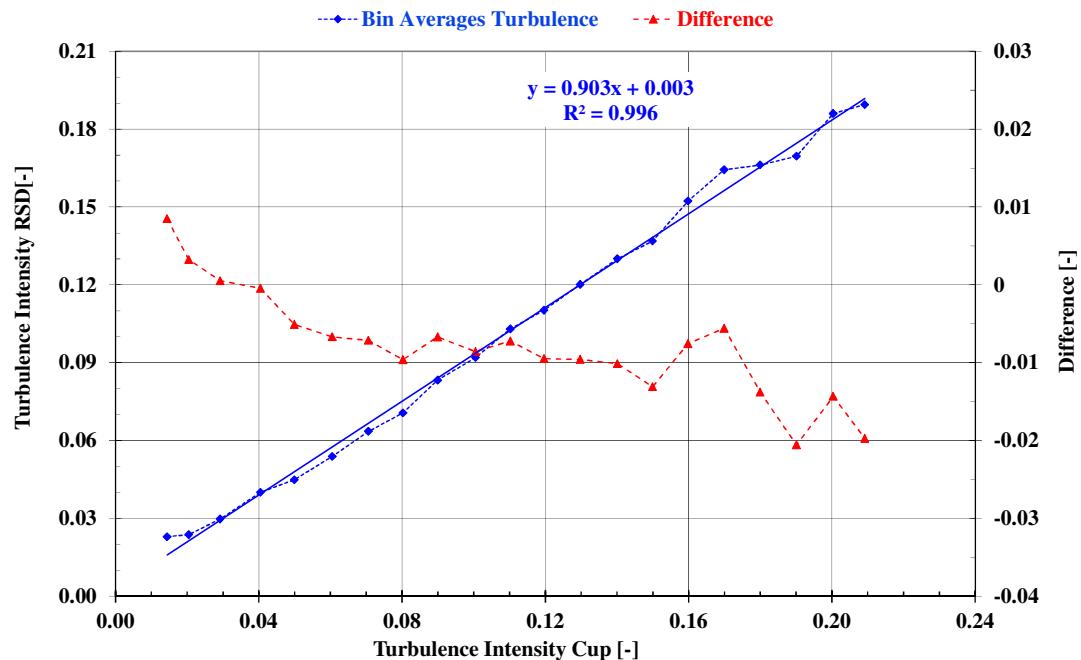

Figure 4.30: Bin analysis of Turbulence Intensity measured by RSD against cup anemometer measurements at 134.75 m height above ground. A positive sign of the shown deviation represents higher values measured by RSD.

Table 4.20 Bin analysis of Turbulence Intensity measured by RSD against cup anemometer measurements at 40.75 m height above ground. A positive sign of the shown deviation represents higher values measured by RSD. The right column shows the total expanded uncertainty (k=2) of the RSD as derived from the test.

4.5 Accuracy of the RSD in Terms of Wind Direction

The wind direction as measured by the RSD and by the met mast is compared for measurement heights of 134.75 m , 100.75 m, 120.75 m, 81.75 m, 60.75 m and 40.75 m in the following sub chapter. The following conclusions can be drawn:

- The wind direction as measured by the RSD and by the vane correlates very good with squared correlation coefficient of 0.999.
- The RSD shows value of mean deviation of -1.86° to 0.29°.
- Overall, the wind direction measurement of the RSD is considered as fine.

4.5.1 Accuracy of Wind Direction at 134.75 m Height

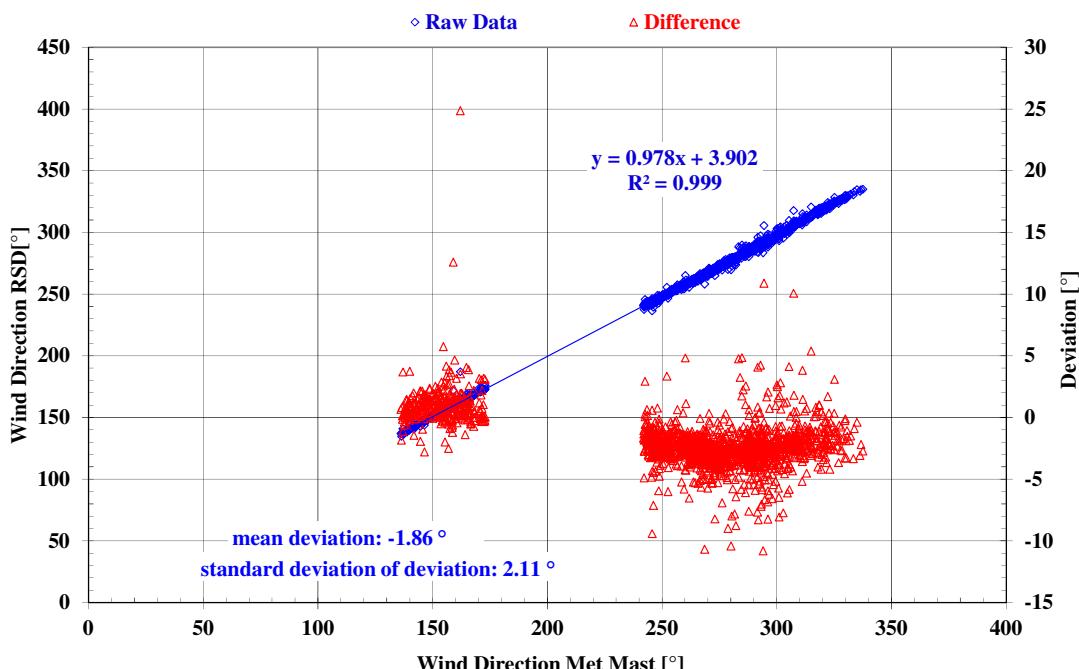

Figure 4.43: Scatter plot of wind direction as measured by RSD at 134.75 m height above ground against vane readings at 129 m measurement height.

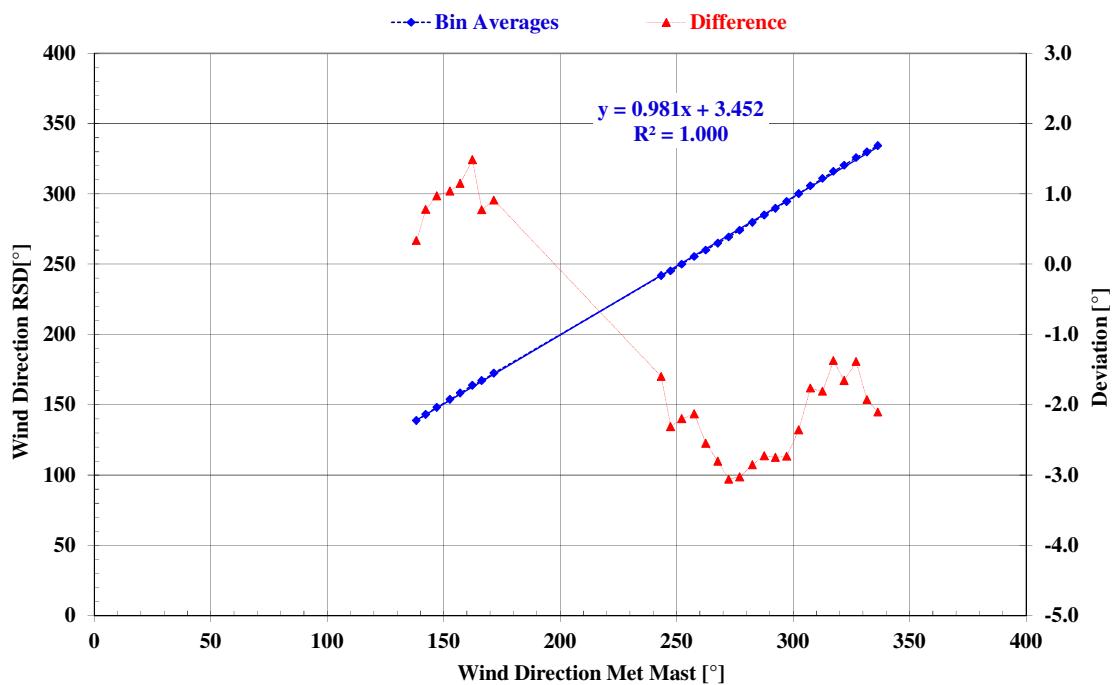

Figure 4.44: Bin analysis of wind direction as measured by RSD at 134.75 m height above ground against vane readings at 129 m measurement height.

A positive sign of the shown deviation represents higher values measured by RSD. The right column shows the total expanded uncertainty (k=2) of the RSD as derived from the test.

5 Conclusions

The accuracy of the lidar of type Molas B300, serial number 4, has been tested against cup anemometers mounted between 40 m and 135 m measurement height on a 135 m high met tower in flat terrain. The met mast is equipped with cup anemometers of high accuracy class and vanes at height levels of about 135 m, 131 m, 120 m, 100 m, 80 m 60 m 40 m and 20 m. All anemometers have been calibrated according to MEASNET by Deutsche WindGuard Wind Tunnel Services GmbH. The respective wind tunnel of Deutsche WindGuard is applied by the German Authority for the standardisation of units, Physikalisch-Technische Bundesanstalt (PTB), as German reference for the definition of the unit m/s in airflow measurements. A more accurate reference for cup anemometers is not available. The anemometers on the mast are mounted according to IEC 61400-12-1 [1]. Mast influences at the lower measurement heights like blockage and flow acceleration effects have been corrected empirically. Wind directions with the sensors of the mast or with the RSD in wakes of the mast or of neighbouring wind turbines have been excluded from the test.

The data evaluation covers a calibration, which describes the accuracy of the tested lidar unit under the conditions during the test.

The main results of the calibration are:

- Depending on measurement height, the database consists of 1470 to 1810 10-minute datasets (1080 are required).
- The RSD shows a very good data availability of more than 99% for measurement heights up to 140m.
- The RSD shows an excellent correlation to cup anemometer measurements in terms of 10-minute averages of the horizontal wind speed component. At heights 135 m to 40 m measurement height the square of correlation coefficient about 0.99.
- For the tested measurement heights between 60 m to 135 m the RSD shows a marginal underestimation of the horizontal wind speed component with a mean deviation of -0.1 to -0.4% or -0.01 to -0.04 m/s.
- The resulting wind speed dependent uncertainties of the measurements of the horizontal wind speed component by the RSD are in the order of about 2% (expanded uncertainty $k=2$) in most wind speed bins for all measurement heights which is considered as good. The variation of the uncertainty reaches from 1.7% to 8.2% (expanded uncertainty $k=2$) for the different measurement heights and wind speed bins.
- The wind direction as measured by the RSD correlates very well to the wind direction as measured by vane on the met mast (squared correlation coefficient above 0.99).

It is pointed out that all shown uncertainties of the measurement of the RSD represent two standard uncertainties (expanded uncertainty $k=2$) as it is required according to DWG's accreditation for calibrations of RSD's. In contrast to that, it is common practice to apply only the single standard uncertainty of wind measurements for most applications throughout the wind energy industry as for instance in case of wind resource assessments or wind turbine power curve tests.
